Explorative Placebo-Controlled Double-Blind Intervention Study with Low Doses of Inhaled Δ9-Tetrahydrocannabinol and Cannabidiol Reveals No Effect on Sweet Taste Intensity Perception and Liking in Humans

Suzanne E.M. de Bruijn, Cees de Graaf, Renger F. Witkamp, and Gerry Jager*

Abstract

Introduction: The endocannabinoid system (ECS) plays an important role in food reward. For example, in humans, liking of palatable foods is assumed to be modulated by endocannabinoid activity. Studies in rodents suggest that the ECS also plays a role in sweet taste intensity perception, but it is unknown to what extent this can be extrapolated to humans. Therefore, this study aimed at elucidating whether Δ9-tetrahydrocannabinol (THC) or cannabidiol (CBD) affects sweet taste intensity perception and liking in humans, potentially resulting in alterations in food preferences.

Materials and Methods: In a randomized placebo-controlled, double-blind crossover study, 10 healthy males participated in three test sessions that were 2 weeks apart. During the test sessions, participants received THC-rich, CBD-rich, or placebo Cannabis by inhalation divided over two doses (4 + 1 mg THC; 25 + 10 mg CBD). Participants tasted seven chocolate milk-like drinks that differed in sugar concentration and they rated sweet taste intensity and liking of the drinks. They were then asked to rank the seven drinks according to how much they liked the drinks and were offered ad libitum access to their favorite drink. In addition, they completed a computerized food preference task and completed an appetite questionnaire at the start, midway, and end of the test sessions.

Results: Inhalation of the Cannabis preparations did not affect sweet taste intensity perception and liking, ranking order, or ad libitum consumption of the favorite drink. In addition, food preferences were not influenced by the interventions. Reported fullness was lower, whereas desire to eat was higher throughout the THC compared to the CBD condition.

Conclusions: These results suggest that administration of Cannabis preparations at the low doses tested does not affect sweet taste intensity perception and liking, nor does it influence food preferences in humans.

Keywords: cannabidiol; food preferences; phytocannabinoids; sweet taste; tetrahydrocannabinol

Introduction

There is growing evidence that the endocannabinoid system (ECS) plays an important role in the regulation of hedonic hunger, that is, consuming foods for the experience of reward and not for the compensation of any energy deficit. More specifically, the ECS seems to modulate palatability-dependent appetite, although the underlying mechanisms are far from clear.

It is important to note that palatability, or pleasantness, is not a fixed function of the sensory properties
and intake,21–25 a phenomenon colloquially known as intake,12,13 possibly through indirect antagonism of the concentration of cannabidiol (CBD) decreases food intake.16,17 Taken together, it is clear that CBD is far from being a classical ligand for the CB1 or CB2 receptor. The molecule displays a wide spectrum of activities on various molecular targets and produces multiple pharmacological effects.15,18

Administration of endocannabinoids was found to specifically increase responses to sweet taste in the Chorda tympani, the nerve that innervates the tongue, in wild-type mice, but not in CB1 knockout mice.19 Administration of a CB1 antagonist decreased responses to sweet taste in the Chorda tympani.20 Together, these results suggest that modulating the ECS selectively changes the psychophysical function for sweet taste in mice.

In humans, anecdotal evidence suggests that the use of Cannabis preparations increases food palatability and intake,21–25 a phenomenon colloquially known as “the munchies.” Furthermore, the CB1 inverse agonist rimonabant decreases food intake.26,27 Thus far, only one study examined the effects of oral administration of Δ9-tetrahydrocannabinol (THC) on taste intensity and liking in humans. In a double-blind placebo-controlled study, acute Cannabis administration was found not to affect taste intensity perception and liking for sweet, sour, salty, and bitter food stimuli at baseline, and 2, 4, and 6 h postdosing. However, THC bioavailability varied widely and THC could not be detected in plasma of all participants.28 Based on the limited number of studies performed in humans, the aim of this study was to further investigate whether modulating the ECS by administering phytocannabinoid preparations affects sweet taste intensity perception and liking in humans, and whether this results in altered food preferences.

Methods
Participants
Ten healthy, normal weight (body mass index = 21.7 ± 1.2 kg/m²) males aged 23.4 ± 1 years participated in this study. Participants were incidental Cannabis users to ensure familiarity with the psychotropic effects of Cannabis use. Frequency of use ranged from four times a year to once a week. To limit the risk of adverse events, males were excluded from participation when they had ever experienced negative effects from using Cannabis (e.g., bad trip, Cannabis-induced psychosis). Other exclusion criteria were restraint eating (Dutch eating behavior questionnaire: score >2.9),29 lack of appetite, difficulties swallowing or eating, having taste or smell disorders (self-report), following an energy-restricted diet 2 months before the study, weight change >5 kg during the 2 months before the study, and being allergic or intolerant to the products under study. Participants were instructed to abstain from Cannabis from 2 weeks before the first test session until study completion. Compliance was tested by means of a urine sample (SureScreen Diagnostics Ltd.) at the beginning of each test session. Participants were also asked not to use alcohol in the 2 days before a test session and not to eat or drink anything except water or weak tea during the 2 h before a test session. Participants gave written informed consent before the start of the study and they received financial compensation for participation.

Design and procedures
The study had a randomized, placebo-controlled, double-blind crossover design. All participants completed one practice session (familiarization with the test procedures) and three test sessions after administration of Cannabis rich in THC, CBD, or placebo (for details see section “Study drugs and administration”). Test sessions were 2 weeks apart to allow for complete clearance of drugs.
Each test session consisted of repeated measurements of appetite and subjective effects using Visual Analogue Scales (VAS), venous blood sampling to determine plasma concentrations of THC and CBD, a taste test with chocolate milk-like drinks that differed in sugar concentration (for details see section “Sweet taste intensity perception and liking”), a control task, a ranking test with the drinks, \textit{ad libitum} intake of the preferred chocolate milk-like drink, and the Macronutrient and Taste Preference Ranking Task (MTPRT). See Figure 1 for a schematic overview of the test procedure.

**Study drugs and administration**

The active preparations consisted of the dried, milled, and homogenized flowers of two varieties of the plant \textit{Cannabis sativa} and were obtained from the Office for Medicinal Cannabis (OMC; The Netherlands), variety Bedrocan\textsuperscript{\textregistered} (19\% THC, <1\% CBD) and variety Bedrolite\textsuperscript{\textregistered} (<1\% THC, 9\% CBD). The placebo (variety “Bedrocan”; <0.5\% THC) had a moisture content and terpenoid profile (providing the typical smell and taste of \textit{Cannabis}) identical to the active drug, and was obtained from Bedrocan BV (official supplier to the OMC). From here onward, we will refer to the three treatments as the THC (Bedrocan), CBD (Bedrolite), and placebo condition. In the THC condition, participants received an initial dose of 4 mg of THC, followed by 1 mg of THC as a top-up dose after 35 min to maintain stable levels of central nervous system effects. In the CBD condition, the initial and top-up dose of CBD were 25 and 10 mg, respectively.

For each individual dose, exact amounts of Bedrocan or Bedrolite and placebo were mixed so that each dose was equal to 250 mg of plant preparation total weight. According to Good Manufacturing Practice guidelines and to ensure double-blindness, study medication was prepared, packed, and coded by ACE Pharmaceuticals BV (Zeeuwolde, The Netherlands), a company licenced to prepare trial medication. Study medication was stored at a temperature of $-18^\circ$C and taken out of the freezer 30 min before the start of a test session. Administration was performed with a MINIVAP vaporizer (Hermes Medical Engineering, S.L.) that was set at a temperature of 230°C. For each administration, participants were instructed to inhale 12 times with a duration of 5 sec per inhalation and a pause of 25 sec between adjacent inhalations.

**Plasma levels and subjective effects**

Venous blood samples were collected in NaF/KOx (anticoagulant) tubes at baseline ($T=0$), $T=30$, and $T=75$ min, and stored at 4°C until the end of the test session. Then, tubes were centrifuged at 1300 $\times$ 10 min at 4°C and plasma samples were collected and stored at $-80^\circ$C until analyses. Plasma was analyzed for THC and CBD concentrations (ng/mL) using liquid chromatography–mass spectrometry/mass spectrometry by Analytical Biochemical Laboratory BV (Assen, The Netherlands). Due to budget restraints, the samples of the placebo condition were only analyzed for half of the sample ($n=5$).

Subjective effects of the treatments were assessed with a VAS on which participants rated “feeling high” throughout the test sessions.

**Sweet taste intensity perception and liking**

A series of chocolate milk-like drinks that differed in sugar concentration was used to assess sweet taste intensity perception and liking. Samples were prepared freshly on the

The basic drink contained 2 g/100 mL added vanilla sugar.

morning of each test session. First, a basic drink was prepared, containing vanilla sugar (Ruf; 2%), Nutilis powder (Nutricia; 3%), cream (De Zaanse Hoeve; 18%), skimmed milk (De Zaanse Hoeve; 74.5%), and cocoa powder (Blooker; 2.5%). Then, different amounts of basic chocolate milk-like drink and sucrose (Van Gilse) were mixed to get seven drinks with 2, 4.4, 6.7, 10, 15, 22.5, and 33.8 g of added sugar per 100 mL, respectively (Table 1). These sugar concentrations were chosen to cover a full psychophysical sweetness intensity curve, ranging from not that sweet to very sweet. The drinks were coded with random three-digit numbers and presented to the participants in 20 mL samples, in a random order that differed between participants, but was kept constant per participant across test sessions. Participants were instructed to take a sip and then first rate sweet taste liking, followed by sweet taste intensity on a 200-point labeled affective magnitude scale33 and a 100-point labeled magnitude scale,34 respectively. In between samples, participants were instructed to rinse their mouth with water and wait 30 sec before tasting the next sample.

Control task
To check whether the Cannabis treatments did not affect task performance or perception in general, a control task was added to the procedures. Participants were asked to rate the grayness of seven shades of gray on a 100-point VAS that was anchored by “white” and “black.”38 Reflection percentages of the different shades were 96%, 84%, 64%, 44%, 20%, 8%, and 4%, respectively, with shades ranging from almost white to almost black. Analyses showed that ratings did not differ between conditions and participants were able to differentiate between the different shades of gray (results not reported).

Appetite, ranking task, and ad libitum intake
Throughout the test sessions, participants thrice (see Fig. 1) rated levels of hunger, fullness, desire to eat, and prospective consumption on a 100-point VAS anchored by “not at all” and “extremely”, except for prospective consumption, which was anchored by “nothing at all” and “a very large amount.”35

After the control task, participants were presented with 80 mL of the seven chocolate milk-like drinks and were asked to rank them according to how much they liked the drinks. During the ad libitum intake test, participants were presented with 1 L of their favorite drink, which they could consume ad libitum for 10 min.

Food preferences
Food preferences were assessed using the MTPRT. In this task, participants were presented with four pictures of different food products at a time and asked to rank the products according to what they most desire to eat at that moment. Food products included in this task were high in carbohydrate, high in fat, high in protein, or low in energy, and had a sweet or savory taste. Examples of foods included in the food preference test are pancakes (high-carbohydrate sweet), salty sticks (high-carbohydrate savory), chocolate bar (high-fat sweet), cheese cubes (high-fat savory), shrimps (high-protein), strawberries (low-energy sweet), and cucumber (low-energy savory). In short, the task consists of a macronutrient section, in which participants are presented with one product from each of the four macronutrient categories, and a taste section, in which participants are presented with two sweet and two savory products. Based on the rankings, preference scores for different macronutrient and taste categories, that is, high-carbohydrate, high-fat, high-protein, and low-energy, and sweet and savory are calculated as described elsewhere.30 Preference scores for the macronutrient categories can range from 1 to 4, with a higher score indicating a higher preference for a category. A score of 1 indicates all products from that category were ranked last and a score of 4 indicates all products from that category were ranked first. As each ranking in the taste section comprises two sweet and two savory products, preference scores for sweet and savory can range from 1.5 to 3.5. Because preference scores for sweet and savory are each other’s opposite, we only report preference scores for sweet in this article.

Data analyses
Data are presented as mean with standard error of the mean. Data were analyzed using IBM SPSS 22 (IBM Corporation). Results were considered statistically significant at \( p < 0.05 \). When statistically significant main effects were found, post-hoc tests were performed using Bonferroni correction.
Liking ratings of the chocolate milk-like drinks were transferred to 100 points by dividing the scores by two. Using repeated measures analysis of variance (ANOVA), rated sweetness intensity and liking of the drinks were compared, with condition (THC, CBD, and placebo) and sugar concentration as factors. For the ranking task, the mean rank was calculated for each chocolate milk-like drink in each condition. Friedman ANOVA was used to compare mean ranks between conditions for each drink separately and ranks of the drinks within conditions. For the ad libitum task, the consumed amount and energy content of the consumed drink were used to calculate the consumed energy. Repeated measures ANOVA was used to test if the consumed energy differed between conditions.

Preference scores from the MTPRT were compared between conditions using repeated measures ANOVA. To compare preference scores within each condition, Friedman ANOVA was used for the macronutrient categories and Wilcoxon signed rank tests were used to compare the sweet and savory preference scores.

Appetite ratings were compared using repeated measures ANOVA with condition (THC, CBD, and placebo) and time as factors. Because of one missing data point for one participant, mixed models ANOVA was used to analyze “feeling high” with condition, time, and condition×time as fixed factors and subject as a random factor.

Results
Plasma levels and subjective effects
Table 2 shows the mean TCH and CBD plasma levels for all three conditions. In some participants, low levels of CBD were detected in the THC condition and vice versa. Low levels of THC were detected in plasma samples after administration of placebo, but these were 8- versus 6.5-fold lower compared to T=30 and T=75 min in the THC condition.

As shown in Figure 2, reported levels of “feeling high” differed between conditions, F(2,13) = 4.60, p < 0.05, and over time, F(4,22) = 7.35, p < 0.05. Post-hoc analyses showed that participants felt significantly more “high” in the THC compared to the placebo condition.

For the second arrow: 1 mg THC, 10 mg CBD or placebo. *Indicates significant difference from T=0 (p < 0.05). **Indicates difference between THC and placebo conditions (p < 0.05). PLA, placebo; SEM, standard error of the mean.
Sweet taste intensity perception and liking
Drinks that contained more sugar were perceived as more sweet, \( F(6,54) = 57.87, p < 0.05 \), but the perceived sweet taste intensity of the seven chocolate milk-like drinks did not differ between the three conditions, \( F(2,18) = 0.66, p = 0.53 \) (Fig. 3A). Liking of different drinks differed with sugar concentration, \( F(6,54) = 2.47, p < 0.05 \), where the drinks that contained the least and the most sugar were liked least. Similar to the intensity findings, the liking of the seven drinks did not differ between conditions, \( F(2,18) = 0.94, p = 0.41 \) (Fig. 3B).

Ranking task
Ranks of the different drinks did not differ between conditions, all \( p > 0.05 \). In addition, the ranking task did not show differences between the drinks, \( \chi^2(6) = 11.10, p = 0.085 \), \( \chi^2(6) = 12.73, p = 0.048 \), and \( \chi^2(6) = 12.51, p = 0.051 \) for THC, CBD, and placebo, respectively.

Appetite and ad libitum intake
Results from the appetite questionnaire can be found in Figure 4. Reported hunger did not differ between conditions, \( F(2,18) = 2.62, p = 0.10 \), and did not change over time, \( F(2,18) = 2.47, p = 0.11 \). However, reported fullness differed between conditions, \( F(2,18) = 3.74, p < 0.05 \), and changed over time, \( F(2,18) = 4.38, p < 0.05 \). Throughout the whole test session, fullness ratings were higher in the CBD condition than in the THC condition. Desire to eat differed between conditions, \( F(2,18) = 6.50, p < 0.05 \), and was higher in the THC condition than in the CBD condition throughout the whole test session, but did not change over time, \( F(2,18) = 2.43, p = 0.12 \). Prospective consumption differed between conditions, \( F(2,18) = 4.83, p < 0.05 \), but did not change over time, \( F(2,18) = 3.34, p = 0.06 \).

Ad libitum intake of the most liked chocolate milk-like drink did not differ between conditions, \( F(2,18) = 0.50, p = 0.62 \). Participants consumed on average 537 ± 67 kcal in the THC condition, 581 ± 66 kcal in the CBD condition, and 595 ± 65 kcal in the placebo condition.

Food preferences
The preference scores can be found in Table 3. Treatments did not affect preference for sweet or for any of the macronutrients, all \( p > 0.05 \). In all three conditions, participants had a preference for savory over sweet, all \( p < 0.05 \), but not for one of the macronutrients over the others, all \( p > 0.05 \).

Discussion
To the best of our knowledge, this study is the first randomized, placebo-controlled double-blind study investigating sweet taste intensity perception, sweet taste liking, and possible consequent changes in food preference following inhalation of THC and CBD. The results indicate no change in sweet taste intensity perception and liking, nor in food preferences, as related to taste (sweet vs. savory) and macronutrient composition (carbohydrate, protein, fat, and low energy).

The lack of effects on sweet taste intensity and liking after activating or inhibiting the ECS is contradictory to our expectations based on previous studies that showed endocannabinoid modulation of sweet taste intensity perception in mice.\(^{19,20}\) However, the current findings...
are in line with a study in humans that assessed taste intensity perception after oral THC administration. In that study, THC did not affect intensity and liking of sweetness, saltiness, sourness, and bitterness.28

In line with the results from the taste test, preference for sweet taste in the MTPRT did not differ between the THC, CBD, and placebo conditions. In addition, preference for macronutrients was not affected by the administration of THC or CBD. Earlier studies in humans showed that Cannabis increases intake of snack foods, with a specific increased intake of sweet snacks.21,22

In this study, participants had a preference for savory over sweet. Just before completing the MTPRT, participants had consumed a large amount of a sweet drink to satiety. This might have caused sensory-specific satiety, that is, decreased pleasantness of sensory properties of the food that has just been consumed to satiety.36 The effect of sensory-specific satiety might have overruled a potential effect of endocannabinoid modulation on preference for sweet taste. However, given that THC and CBD administration did not influence sweet taste intensity perception and liking of the chocolate milk-like drinks, we think it is more likely that there is no effect of endocannabinoid modulation on sweet taste preference.

Desire to eat was higher and fullness was lower in the THC condition compared to the CBD condition, possibly

Values are mean ± SEM. Preference scores for macronutrient categories can range between 1 and 4, preference score for sweet can range between 1.5 and 3.5.
related to baseline differences. However, despite these differences, ad libitum intake of the most preferred chocolate milk-like drink did not differ between conditions. In a previous study in cancer patients, THC treatment increased appetite, but did not affect total energy intake. Also, in a healthy population, THC did not affect the total energy intake. However, other studies in humans showed that THC increases food intake. CBD has previously been shown not to affect appetite in patients who suffer from type 2 diabetes. In rats, however, CBD has been shown to decrease food intake, which may be caused by higher fullness. These contradicting findings warrant further investigation.

The plasma levels of THC and CBD showed that the administration of pharmacological doses by inhalation was successful in our study. The placebo Cannabis contained traces of THC, which led to detectable, but very low, THC plasma levels in the placebo condition. As THC plasma levels in the placebo condition were eight times lower than in the THC condition, the functional consequences on outcome measures are likely minimal.

The relatively small sample size could be regarded as a limitation of our exploratory study. However, we would expect to find similar results in a larger sample. With 10 participants, we see a great overlap of the mean sweet taste intensity and liking of the different drinks, which suggests that we will also not see any differences with more participants included in the study. Especially for the sweet taste liking, there is a large variation between participants. For the food preference task, one may expect to find differences in preference for low-energy products with a larger sample size. As CBD increases fullness and decreases desire to eat, we would expect that it also increases preference for low-energy products based on previous experience with the MTPRT.

This study included only male participants. As endocannabinoid pharmacology differs between males and females, females might respond differently to inhaled THC and CBD. Future studies should take this into account and consider to include both males and females.

Another plausible explanation for our negative results might be that we used a relatively low dose of THC compared to other studies. We chose this dose as we did not want obvious intoxication to influence the results. However, it is possible that the dose is too low to evoke an effect and we would have seen an effect of THC on sweet taste intensity perception and liking if we would have used a higher dose. Importantly, the effects of THC and other CB1 agonists usually follow an inverted U-shape, that is, there is an optimal dose at which the largest effect occurs and for higher doses, the effect wears off. Dosing too high could therefore also lead to no effect. Future studies should take this into consideration.

Based on the results from this study, we conclude that challenging the ECS with low doses of THC or CBD does not influence sweet taste intensity perception and liking in humans. In addition, low doses of THC and CBD do not affect food preferences.

Acknowledgments
We would like to thank Pauline Claessen, research dietician, for providing the recipe for the chocolate milk-like drinks, and Tim Crolla and Michele Pedrotti for their help in carrying out the study. Research presented in this publication was financially supported by the Graduate School VLAG.
